A cancellation

Figure: Cancellation of 3 sell orders at 69900.
Stochastic models for order book dynamics enable to

- Incorporate the information in
  1. the current state of the order book
  2. statistics on the order flow (arrival rates of market, limit orders and cancellation)

in view of

1. optimal order execution
2. intraday modeling and prediction of price changes and volatility

under statistically realistic assumptions on the order flow.
These applications requires *analytical* tractability and computability.
Limit order books as queueing systems

A limit order book may be viewed as a system of queues subject to order book events modeled as a multidimensional point process. A variety of stochastic models for dynamics of order book events and/or trade durations at high frequency:

- Independent Poisson processes for each order type (Cont Stoikov Talreja 2010)
- Self exciting and mutually exciting Hawkes processes (Andersen, Cont & Vinkovskaya 2010, Bacry et al 2010)
- Autoregressive Conditional Duration (ACD) model (Engle & Russell 1997, Engle & Lunde 2003, ..)

Aim: reproducing empirical properties (Smith et al, 2003, Bouchaud et al 08) for prediction, trade execution, intraday risk management. Any of these models implies some dynamics for the (bid/ask) price, but which is difficult to describe explicitly.

In general: price is not Markovian, increments neither independent nor stationary and depend on the state of the order book.
Time scales

Table: A hierarchy of time scales.

Idea: start from a description of the limit order book at the finest scale and use asymptotics/limit theorems to derive quantities at larger time scales. Analogous to hydrodynamic limits used in the study of interacting particle systems.
A reduced-form model for the limit order book

- If one is primarily interested in price dynamics, the 'action' takes place at the best bid/ask levels.
- In fact, empirical data show that the bulk of orders flow to the queues at the best bid/ask (e.g., Biais, Hillion & Spatt 1995).
- Ask price: best selling price: $s^a = (s^a_t, t \geq 0)$
- Bid price: best buying price $s^b = (s^b_t, t \geq 0)$.
- Reduced modeling framework: state variables = number of orders at the ask: $(q^a_t, t \geq 0)$.
- and number of orders at the bid: $(q^b_t, t \geq 0)$.

State variable: $(s^b_t, q^b_t, s^a_t, q^a_t)_{t \geq 0}$.
Figure: Reduced-form representation of a limit order book
Limit order book as reservoir of liquidity

Once the bid (resp. the ask) queue is depleted, the price moves to the queue at the next level, which we assume to be one tick below (resp. above).

The new queue size then corresponds to what was previously the number of orders sitting at the price immediately below (resp. above) the best bid (resp. ask).

Instead of keeping track of these queues (and the corresponding order flow) at all price levels we treat the new queue sizes as independent variables drawn from a certain distribution \( f \) where \( f(x, y) \) represents the probability of observing \((q^b_t, q^a_t) = (x, y)\) right after a price increase. Similarly, after a price decrease \((q^b_t, q^a_t)\) is drawn from a distribution \( \tilde{f} \neq f \) in general.

- if \( q^a_{t_0} = 0 \) then \((q^b_t, q^a_t)\) is a random variable with distribution \( f \), independent from \( \mathcal{F}_{t_0} \).
- if \( q^b_{t_0} = 0 \) then \((q^b_t, q^a_t)\) is a random variable with distribution \( \tilde{f} \), independent from \( \mathcal{F}_{t_0} \).
Distribution of queue sizes after a price move

Figure: Joint density of bid and ask queues after a price move.
Distribution of queue sizes after a price move

Figure: Joint density of bid and ask queues after a price move: log-scale
Distribution of queue sizes after a price move

We can parameterize this distribution $F$ through

- a radial component $R = \sqrt{|Q^b|^2 + |Q^a|^2}$, which measures the depth of the order book, and
- an angular component $\Theta = \arctan(Q^a/Q^b) \in [0, \pi/2]$ which measures the *imbalance* between outstanding buy and sell orders.

A flexible model which allows for analytical tractability is to assume

$$F(x, y) = H(\sqrt{x^2 + y^2})G\left(\arctan\left(\frac{y}{x}\right)\right) \quad (1)$$

where $H$ is a probability distributions on $\mathbb{R}_+$ and $G$ a probability distributions on $[0, \pi/2]$.

Figure: Distribution of lifetime (in ms) of a spread larger than one tick (left), equal to one tick (right).
Given these observations, we assume for simplicity that the spread is constant, equal to one tick:

\[ \forall t \geq 0, s_t^a = s_t^b + \delta. \]

This assumption of constant spread is justified at a time scale beyond 10 milliseconds, since for many liquid stocks, the lifetime of a spread \(> 1 \text{ tick} \) is \(\sim\) a few milliseconds, while the lifetime of a 1-tick spread is \(\sim\) seconds. This assumptions allows to deduce price dynamics from the dynamics of the order book:

- Price decreases by \(\delta\) when bid queue is depleted:
  \[ q_{t-}^b = 0 \Rightarrow s_t = s_{t-} - \delta \]

- Price increases by \(\delta\) when ask queue is depleted:
  \[ q_{t-}^a = 0 \Rightarrow s_t = s_{t-} + \delta \]
Summary: dynamics of bid / ask queues and price

The process $X_t = (s_t^b, q_t^b, q_t^a)$ is thus a continuous-time process with piecewise constant sample paths whose transitions correspond to the order book events at the ask $\{t_i^a, i \geq 1\}$ or the bid $\{t_i^b, i \geq 1\}$ with (random) sizes $(V_i^a)_{i \geq 1}$ and $(V_i^b)_{i \geq 1}$.

- Order or cancelation arrives on the ask side $t \in \{t_i^a, i \geq 1\}$:
  - If $q_{t-}^a + V_i^a > 0$: $q_t^a = q_{t-}^a + V_i^a$, no price move.
  - If $q_{t-}^a + V_i^a \leq 0$: price increases $S_t = S_{t-} + \delta$, queues are regenerated $(q_t^b, q_t^a) = (R_i^b, R_i^a)$ where $(R_i^a, R_i^b)_{i \geq 1}$ are IID variables with (joint) distribution $f$

- Order or cancelation arrives on the bid side $t \in \{t_i^b, i \geq 1\}$:
  - If $q_{t-}^b + V_i^b > 0$: $q_t^a = q_{t-}^a + V_i^a$, no price move.
  - If $q_{t-}^b + V_i^b \leq 0$: price decreases $S_t = S_{t-} - \delta$, queues are regenerated $(q_t^b, q_t^a) = (\tilde{R}_i^b, \tilde{R}_i^a)$ where $(\tilde{R}_i)_{i \geq 1} = (\tilde{R}_i^a, \tilde{R}_i^b)_{i \geq 1}$ is a sequence of IID variables with (joint) distribution $\tilde{f}$
Example: a Markovian limit order book

- Market buy (resp. sell) orders arrive at independent, exponential times with rate $\mu$,
- Limit buy (resp. sell) orders arrive at independent, exponential times with rate $\lambda$,
- Cancellations orders arrive at independent, exponential times with rate $\theta$.
- The above events are mutually independent.
- All orders sizes are constant.

$\rightarrow$ Poisson point process $\Rightarrow$ explicit computations possible
Between price changes, \((q^a_t, q^b_t)\) are independent birth and death process with birth rate \(\lambda\) and death rate \(\mu + \theta\).

Let \(\sigma^a\) (resp. \(\sigma^b\)) be the first time the size of the ask (resp bid) queue reaches zero. Duration until next price move: \(\tau = \sigma^a \wedge \sigma^b\)

These are hitting times of a birth and death process so conditional Laplace transform of \(\sigma^a\) solves:

\[
\mathcal{L}(s, x) = \mathbb{E}[e^{-s\sigma^a} | q_0^a = x] = \frac{\lambda \mathcal{L}(s, x + 1) + (\mu + \theta) \mathcal{L}(s, x - 1)}{\lambda + \mu + \theta + s},
\]

We obtain the following expression for the (conditional) Laplace transform of \(\sigma^a\):

\[
\mathcal{L}(s, x) = \left(\frac{\lambda + \mu + \theta + s}{2\lambda} - \sqrt{((\lambda + \mu + \theta + s))^2 - 4\lambda(\mu + \theta)}\right)^x.
\]
Duration until the next price change

- The duration $\tau$ until the next price change is given by:
  \[ \tau = \sigma^a \land \sigma^b. \]

- The distribution of $\tau$ conditional on the current queue sizes is
  \[ \mathbb{P}[\tau > t | q^a_0 = x, q^b_0 = y] = \mathbb{P}[\sigma^a > t | q^a_0 = x] \mathbb{P}[\sigma^b > t | q^b_0 = y]. \]

- Inverting the Laplace transforms of $\sigma^a, \sigma^b$ we obtain
  \[ \mathbb{P}[\tau > t | q^a_0 = x, q^b_0 = y] = \int_t^\infty \hat{L}(u, x) du \int_t^\infty \hat{L}(u, y) du, \]
  where
  \[ \hat{L}(t, x) = \sqrt{\left( \frac{\mu + \theta}{\lambda} \right)x} \frac{x}{t} l_x(2\sqrt{\lambda(\theta + \mu)t})e^{-t(\lambda+\theta+\mu)}. \]
Duration until next price move

- Littlewood & Karamata’s Tauberian theorems links the tail behavior of $\tau$ to the behavior of the conditional Laplace transforms of $\sigma^a$ and $\sigma^b$ at zero.
- When $\lambda < \theta + \mu$
  - $\mathbb{P}[\sigma^a > t | q^a_0 = x] \sim_{t \to \infty} \frac{x(\lambda + \mu + \theta)}{2\lambda(\mu + \theta - \lambda)} \frac{1}{t}$
  - $\mathbb{P}[^{\tau > t} q^a = x, q^b_0 = y] \sim_{t \to \infty} \frac{xy(\lambda + \mu + \theta)^2}{\lambda^2(\mu + \theta - \lambda)^2} \frac{1}{4t^2}$.
- Tail index of order 2
- When $\lambda = \theta + \mu$
  - $\mathbb{P}[\sigma^a > t | q^a_0 = x] \sim_{t \to \infty} \frac{x}{\sqrt{\pi \lambda}} \frac{1}{\sqrt{t}}$
  - $\mathbb{P}[^{\tau > t} q^a = x, q^b_0 = y] \sim_{t \to \infty} \frac{x}{\sqrt{\pi \lambda}} \frac{1}{\sqrt{t}}$
- Tail index of order 1: the mean between two consecutive moves of the price is infinite.
Intuitively, *bid-ask imbalance* gives an indication of the direction of short term price moves. This intuition can be quantified in this model:

**Proposition**

When $\lambda = \theta + \mu$, the probability $\phi(n, p)$ that the next price move is an increase, conditioned on having the $n$ orders on the bid side and $p$ orders on the ask side is:

$$
\phi(n, p) = \frac{1}{\pi} \int_0^\pi (2 - \cos(t) - \sqrt{(2 - \cos(t))^2 - 1})^p \frac{\sin(nt) \cos(t/2)}{\sin(t/2)} dt.
$$

Interestingly: this quantity does not depend on the arrival rates $\lambda, \theta, \mu$ as long as $\lambda = \theta + \mu$!
Figure: Conditional probability of a price increase, as a function of the bid and ask queue size (solid curve) compared with transition frequencies for CitiGroup tick-by-tick data on June 26, 2008 (points).
Diffusion limit of the price

At a *tick* time scale the price is a piecewise constant, discrete process. But over larger time scales, prices have “diffusive” dynamics and modeled as such. Consider a time scale over which the average number of order book events is of order $n$, i.e.

$$\frac{T_1 + \ldots + T_n}{t_n} = O(1)$$

We will then show that

$$(s^n_t := \frac{s_{tn}}{\sqrt{n}}, t \geq 0)_{n\geq 1}$$

behaves as a diffusion as for $n$ large and compute its volatility in terms of order flow statistics i.e. a *functional central limit theorem* for $(s^n_t)_{n\geq 1}$. Diffusion limits of queues have been widely studied (Harrison, Reiman, Williams, Iglehart & Whitt,..) but the *price* process has no analogue in queueing theory.
Diffusion limit of the price: balanced order flow

Balanced order book (C & De Larrard (2010))

If $\lambda = \theta + \mu$ then

$$\left(\frac{s(n \log n t)}{\sqrt{n}}\right)_{t \geq 0} \overset{\mathcal{D}}{\Rightarrow} \sqrt{\frac{\pi \lambda \delta^2}{D(f)}} B$$

where $B$ is a Brownian motion, $\sqrt{D(F)} = \sqrt{\int_{\mathbb{R}^2_+} xy \, dF(x, y)}$, the geometric mean of the bid queue and ask queue sizes, is a measure of order book depth after a price change.

When observed at time scale $\tau_2 \gg \tau_0$ representing $n \log(n)$ orders, the price behaves as a diffusion with variance

$$\sigma^2 = \delta^2 \frac{\tau_2}{\tau_0} \frac{\pi \lambda}{D(f)}$$
Linking order flow and volatility

\[ \sigma^2 = \delta^2 \frac{\pi \lambda}{D(f)} \]

- expresses the variance of the price increments in terms of order flow statistics: quantities whose estimation does NOT require to observe the price!
- a means ’microstructure’ affects the volatility only through
  - the arrival rate of orders \( \lambda \)
  - \( D(f) \) average market depth / queue size after a price change

Example: General Electric (GE), June 26 2008.

(Realized) volatility of 10-minute price changes (in annualized vol units):
\( \sigma = 21.78\% \) with 95\% confidence interval: [19.3 ; 23.2] $ 

Our ‘microstructure’ volatility estimator: \( \hat{\sigma} = \delta^2 \pi \lambda n / D(f) = 22.51\% \) $

Not bad for such a simple model!
This is a first step towards incorporating information on order flow into estimators of intraday volatility.
Figure: $\sqrt{\frac{\lambda}{D(f)}}$, estimated from tick-by-tick order flow (vertical axis) vs realized volatility over 10-minute intervals for stocks in the Dow Jones Index, June 26, 2008. Each point represents one stock.
Scaling of volatility with order frequency

\[ \sigma^2 = \delta^2 \frac{\pi \lambda}{D(f)} \]

If we increase the intensity of order by a factor \( x \),

- The intensity of limit orders becomes \( \lambda x \)
- The intensity of market orders and cancelations becomes \( (\mu + \theta)x \)
- The limit order book depth becomes \( x^2 D(f) \).

Our model predicts that volatility is decreased by a factor \( \sqrt{\frac{1}{x}} \).

Rosu (2010) shows the same dependence in \( 1/\sqrt{x} \) of price volatility using an equilibrium approach.
Theorem

When $\lambda < \theta + \mu$ (market orders/cancelations dominate limit orders),

$$
\left( \frac{s(nt)}{\sqrt{n}} \right)_{t \geq 0} \xrightarrow{\mathcal{D}} \delta \sqrt{ \frac{1}{m(f, \theta + \mu, \lambda)} } B
$$

where $B$ is a Brownian motion and $m(f, \theta + \mu, \lambda) = \mathbb{E}[\tau_f]$ is the average time between two consecutive prices moves.
Diffusion limit of the price

**Theorem**

When $\lambda < \theta + \mu$ (market orders/ cancelations dominate limit orders),

$$(\frac{s(nt)}{\sqrt{n}})_{t \geq 0} \overset{D}{\Rightarrow} \delta \sqrt{\frac{1}{m(f, \theta + \mu, \lambda)}} B$$

where $B$ is a Brownian motion and $m(f, \theta + \mu, \lambda) = \mathbb{E}[\tau_f]$ is the average time between two consecutive prices moves.

**Remark**

If $\tau_0$ is the (UHF) time scale of incoming orders and $\tau_2 \gg \tau_0$ the variance of the price increments at time scale $\tau_2$ is

$$\sigma^2 = \frac{\tau_2}{\tau_0} \frac{\delta^2}{m(f, \lambda + \mu, \theta)}$$
Durations are not exponentially distributed.

Figure: Quantile-Plot for inter-event durations, referenced against an exponential distribution. Citigroup June 2008.
Order sizes are heterogeneous

Figure: Number of shares per event for events affecting the ask. Citigroup stock, June 26, 2008.
Beyond Markovian models

This Markovian model is analytically tractable because:

- All orders have the same size (queue)
- The time between two orders is exponential
- The orders arrive at independent times
- The dynamics of the bid is independent from the ask
Beyond Markovian models

This Markovian model is analytically tractable because:

- All orders have the same size (→ queue)
- The time between two orders is exponential
- The orders arrive at independent times
- The dynamics of the bid is independent from the ask

Are the results of this Markovian model robust to these assumptions?
This Markovian model is analytically tractable because:

- All orders have the same size (→ queue)
- The time between two orders is exponential
- The orders arrive at independent times
- The dynamics of the bid is independent from the ask

Are the results of this Markovian model robust to these assumptions?

Answer: in a liquid market, YES, but at a lower frequency!
A general framework for order book dynamics

The dynamics of the order book may be described in terms of:

- $T_i^a$: durations between order book events at the ask
- $V_i^a$: size of the $i$th event at the ask. If the $i$th event is a market order or a cancellation, $V_i^a < 0$; if it is a limit order, $V_i^a \geq 0$.
- $T_i^b$: the time between the $(i-1)$th and the $i$th order coming on the bid side
- $V_i^b$: the size of the $i$th event at the bid

We do not assume these random variables to be independent!

For general sequences $(T_i^a, V_i^a)_{i \geq 0}$ and $(T_i^b, V_i^b)_{i \geq 0}$, the order book $q = (q^a, q^b)$ is not a Markov process.

It is not possible, for general sequences $(T_i^a, V_i^a)_{i \geq 0}$ and $(T_i^b, V_i^b)_{i \geq 0}$, to compute the probability transitions of the price and the distribution of the moving times of the price.
The relevance of asymptotics

Table: Average number of orders in 10 seconds and number of price changes (June 26th, 2008).

These observations point to the relevance of asymptotics when analyzing the dynamics of prices in a limit order market where orders arrivals occur frequently.
Figure: Intraday dynamics of bid and ask queues: Citigroup, June 26, 2008.
From micro- to meso-structure: heavy traffic approximation

- Let $\tau_0$ be the time scale of order arrivals (the millisecond).
- At the time scale $\tau_1 >> \tau_0$, the impact of one order is 'very small' compared to the total number of orders $q^a$ and $q^b$.
- It is reasonable to approximate $q = (q^a, q^b)$ by a process whose state space is continuous ($\mathbb{R}^2_+$).
- More precisely we will show that the rescaled order book

$$Q_n(t) = \left( \frac{q^a(tn)}{\sqrt{n}}, \frac{q^b(tn)}{\sqrt{n}} \right)_{t \geq 0}$$

converges in distribution to a limit heavy traffic approximation of $q = (q^a, q^b) = \text{limit (in distribution)} Q = (Q^a, Q^b)$ of $Q_n$. 

Rama Cont & Adrien de Larrard 
Price Dynamics in Limit Order Markets
Assumptions on the order arrivals

- \((T^a_i, i \geq 1)\) and \((T^b_i, i \geq 1)\) are stationary sequences with

\[
\frac{T^a_1 + T^a_2 + \ldots + T^a_n}{n} \xrightarrow{n \to \infty} \frac{1}{\lambda^a} \quad \frac{T^b_1 + T^b_2 + \ldots + T^b_n}{n} \xrightarrow{n \to \infty} \frac{1}{\lambda^b}
\]

- Examples verifying these assumptions:
  - Independent Poisson processes for each order type (Cont Stoikov Talreja 2010)
  - Self exciting and mutually exciting Hawkes processes (Andersen, Cont & Vinkovskaya 2010)
  - Autoregressive Conditional Duration (ACD) model (Engle & Russell 1997)
Assumptions on order sizes

\((V_i^{n,a}, V_i^{n,b})_{i\geq 1}\) is a stationary, uniformly mixing array of random variables satisfying

\[ \sqrt{n}E[V_1^{a,n}] \xrightarrow{n \to \infty} V^a, \quad \sqrt{n}E[V_1^{b,n}] \xrightarrow{n \to \infty} V^b, \]  

\[ \lim_{n \to \infty} E[(V_i^{n,a} - \overline{V}^a)^2] + 2 \sum_{i=2}^{\infty} \text{cov}(V_1^{n,a}, V_i^{n,a}) = \nu_a^2 < \infty, \quad \text{and} \]

\[ \lim_{n \to \infty} E[(V_i^{n,b} - \overline{V}^b)^2] + 2 \sum_{i=2}^{\infty} \text{cov}(V_1^{n,b}, V_i^{n,b}) = \nu_b^2 < \infty. \]

Under this assumption one can define

\[ \rho := \lim_{n \to \infty} \frac{2 \max(\lambda^a, \lambda^b) \text{cov}(V_1^{n,a}, V_1^{n,b}) + 2 \sum_i \lambda^a \text{cov}(V_1^{n,a}, V_i^{n,b}) + \lambda^b \text{cov}(V_1^{n,b}, V_i^{n,a})}{\nu_a \nu_b} \]

\[ \rho \in (-1, 1) \] may be interpreted as a measure of ‘correlation’ between event sizes at the bid and event sizes at the ask.
Theorem: Order book dynamics in a high-frequency order flow

\[ Q_n = \left( \frac{q^a(tn)}{\sqrt{n}}, \frac{q^b(tn)}{\sqrt{n}} \right)_{t \geq 0} \overset{D}{\rightarrow} Q \quad \text{on} \quad (D, J_1), \]

where \( Q \) is a Markov process on \( \mathbb{R}^2_+ \) with infinitesimal generator

\[ \mathcal{G}h(x, y) = \frac{\delta^2}{2} v^2 \lambda \left( \frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} + 2\rho \frac{\partial^2 h}{\partial x \partial y} \right), \quad \text{for} \quad x > 0, y > 0, \]

whose domain \( D \) is the set of functions \( h \in C^2(\mathbb{R}_+)^2 \) verifying the 'Wentzell boundary conditions': \( \forall x > 0, y > 0, \)

\[ h(x, 0) = \int_{(0, \infty)^2} h(u, v) F(du, dv) \quad h(0, y) = \int_{(0, \infty)^2} h(u, v) \tilde{F}(du, dv) = 0 \]
Heavy traffic limit: technique of proof

Key idea: study the net order flow process

\[ X_t = (x^b_t, x^a_t) = \left( \sum_{i=1}^{N^b_t} V^b_i, \sum_{i=1}^{N^a_t} V^a_i \right) \]

where \( N^b_t \) (resp. \( N^a_t \)) is the number of events (i.e. orders or cancelations) occurring at the bid (resp. the ask) during \([0, t] \).

Step 1: functional Central limit theorem for \( x: x \Rightarrow X \)

Step 2: build \( Q \) from \( X \) by a pathwise construction \( Q = \Psi(X) \) where \( \Psi: D([0, \infty), \mathbb{R}^2) \mapsto D([0, \infty), \mathbb{R}_+^2) \)

Step 3: show continuity of \( \Psi \) for Skorokhod topology \((D, J_1)\) at continuous paths which avoid \((0,0)\).

Step 4: apply continuous mapping theorem \( Q_n = \Psi(x) \Rightarrow Q = \Psi(X) \)
Heavy traffic limit of order book: description

The limit is a Markov process \( Q \) which

- behaves like planar Brownian motion with covariance matrix

\[
\begin{pmatrix}
\lambda_a v_a^2 & \rho \sqrt{\lambda_a \lambda_b} v_a v_b \\
\rho \sqrt{\lambda_a \lambda_b} v_a v_b & \lambda_b v_b^2
\end{pmatrix}
\]  

(3)

on the orthant \( \{x > 0\} \cap \{y > 0\} \)

- jumps to a value with the distribution \( F \) each time it hits the \( x \) axis
- jumps to a value with distribution \( \tilde{F} \) each time it hits the \( y \) axis
Heavy traffic limit: description

Let $\tau_0$ the time scale of incoming orders and $\tau_1 \gg \tau_0$. Under the previous assumptions we can approximate the dynamics of the order book $q = (q^a, q^b)$ by the process $Q$ with covariance matrix

$$
\Sigma = \begin{pmatrix}
\lambda_a v_a^2 & \rho \sqrt{\lambda_a \lambda_b} v_a v_b \\
\rho \sqrt{\lambda_a \lambda_b} v_a v_b & \lambda_b v_b^2
\end{pmatrix}
$$

- $\mathbb{E}[T^a_1] = 1/\lambda_a \quad \mathbb{E}[T^b_1] = 1/\lambda_b$: average duration between events
- $v_a^2 = \mathbb{E}[(V^a_1)^2] + 2 \sum_{i=2}^{\infty} \text{Cov}(V^a_1, V^a_i)$: variance of order sizes at ask
- $\rho$ “correlation” between the order sizes at the bid and at the ask.

If order sizes at bid and ask are symmetric and uncorrelated then $\rho = 0$. **Empirically we find that $\rho < 0$ for all data sets examined.**
Figure: Evolution in time of the bid and ask queues: the queue sizes follow a diffusion-type dynamics in between two price changes and jumps at each price change.
Price dynamics in the heavy traffic limit

Proposition (Cont & De Larrard 2011)

Under the same assumptions

$$(s_{nt}, t \geq 0)^{n \rightarrow \infty} S,$$

where

$$S_t = \sum_{0 \leq s \leq t} 1_{Q^a(t-)=0} - \sum_{0 \leq s \leq t} 1_{Q^b(t-)=0}$$

(5)

is a piecewise constant cadlag process which

- increases by one tick every time the process $(Q(t-), t \geq 0)$ hits the horizontal axis $\{y = 0\}$ and
- decreases by one tick every time $(Q(t-), t \geq 0)$ hits the vertical axis $\{x = 0\}$.

This characterization allows to compute in detail various probabilistic properties of price dynamics and relate them to order flow parameters.
If $V^a = V^b = 0$, $P[\tau > t|Q_0^a = x, Q_0^b = y] =

\sqrt{2U}\frac{U}{\pi t}e^{-\frac{U}{4t}}\sum_{n=0}^{\infty} \frac{1}{(2n+1)} \sin \frac{(2n+1)\pi \theta_0}{\alpha} (I_{(\nu_n-1)/2}(\frac{U}{4t}) + I_{(\nu_n+1)/2}(\frac{U}{4t})),$

where $\nu_n = (2n+1)\pi/\alpha$, $I_n$ is the $n$th Bessel function,

$U = \left(\frac{x}{\lambda_a v_a^2}\right)^2 + \left(\frac{y}{\lambda_b v_b^2}\right)^2 - 2\rho \frac{xy}{\lambda_a \lambda_b v_a^2 v_b^2 (1-\rho)}$, 

$\alpha = \begin{cases} 
\pi + \tan^{-1}(-\frac{\sqrt{1-\rho^2}}{\rho}) & \rho > 0 \\
\tan^{-1}(-\frac{\sqrt{1-\rho^2}}{\rho}) & \rho < 0 
\end{cases}$

$\theta_0 = \begin{cases} 
\pi + \tan^{-1}(-\frac{y \sqrt{1-\rho^2}}{x - \rho y}) & \rho > 0 \\
\tan^{-1}(-\frac{y \sqrt{1-\rho^2}}{x - \rho y}) & \rho < 0 
\end{cases}$
Spitzer (1958) computed the tail index of $\tau$ as a function of the correlation coefficient $\rho$.

The tail index of $\tau$ given $x$ orders at the ask and $y$ orders at the bid is

$$\frac{\pi}{\pi + 2 \arcsin(\rho)}$$

- If $\rho = 0$, the tail index is 1. The tail index was the same for the Markovian order book when $\lambda = \theta + \mu$.
- If $\rho > 0$, the tail index is strictly less than one.
- If $\rho < 0$, the tail index is higher than one: The duration between consecutive price moves has a finite first moment.
Probability of the price moving up

Proposition

(R C & Larrard, 2010): The probability $p_{up}(x, y)$ that the next price move is an increase, given a queue of $x$ shares on the bid side and $y$ shares on the ask side is

$$p_{up}(x, y) = \frac{1}{2} - \frac{\arctan\left(\sqrt{\frac{1+\rho}{1-\rho}} \cdot \frac{y}{\sqrt{\lambda_a v_a}} - \frac{x}{\sqrt{\lambda_b v_b}}\right)}{2 \arctan\left(\sqrt{\frac{1+\rho}{1-\rho}}\right)},$$

(7)

Avellaneda, Stoikov & Reed (2010) computed this for the case $\rho = -1$. When $\rho = 0$ (independent flows at bid and ask)

$$p_{up}(x, y) = 2 \arctan\left(\frac{y}{x}\right)/\pi.$$
Probability of upward price move conditional on queue sizes

![Graph showing the probability of upward price move conditional on queue sizes]
Many econometric models of intraday price dynamics assume the existence of a latent 'true' or 'efficient' price process - assumed to be a martingale- and such that the bid/ask prices are rounded/discretized version of this process.

In our model we can in fact exhibit this process: given the bid/ask queue dynamics, it not latent but a function of \((Q^b_t, Q^a_t)\):

**Proposition (Martingale price)**

If \(p^+ = p^- = 1/2\), then

\[
P_t = S^b_t + \delta(2p^{up}(Q^b_t, Q^a_t) - 1)
\]

is a continuous martingale.

If \(\rho = -1\) this becomes an average of bid/ask prices weighted by queue size, an indicators used by many traders (Burghardt et al):

\[
P_t = \frac{Q^a_t}{Q^a_t + Q^b_t}S^b_t + \frac{Q^b_t}{Q^a_t + Q^b_t}S^a_t.
\]
Diffusion limit of the price

At a *tick* time scale the price is a piecewise constant, discrete process. But over larger time scales, prices are observed to have “diffusive” dynamics and modeled as such. Consider a time scale $t_n$ over which $n$ orders (limit, market, cancel) arrive. Does the rescaled price process

$$s^n_t = \frac{s^{tn}_t}{\sqrt{n}}$$

behave like a diffusion? What is this diffusion limit? How is the “low frequency” volatility of the price related to order flow statistics?

Approach: derive a functional Law of Large Numbers ("fluid limit") and a functional Central Limit theorem for the price process $(s^n_t, t \geq 0)$ as $n \to \infty$
Link between intraday price trend and order flow

Probability of two successive price increases \( p_+ = \int_{\mathbb{R}_+^2} p_{up}(x, y) F(dx \ dy) \)

Probability of successive price decreases
\( p_- = \int_{\mathbb{R}_+^2} (1 - p_{up}(x, y)) \tilde{F}(dx \ dy) \)

Empirically \( p_+ < 1/2, p_- < 1/2 \), due to asymmetry of \( F, \tilde{F} \) which induces mean reversion in the price.

**Theorem (Fluid limit)**

\[
\frac{S(nt)}{n} \to \mu t, \text{ where } \mu \text{ is an intraday trend/drift given by}
\]

\[
\mu = \frac{p_+}{1-p_+} - \frac{p_-}{1-p_-}
\]

\[
\frac{p_+}{1-p_+} \tau_F + \frac{p_-}{1-p_-} \tau_{\tilde{F}}
\]

where \( \tau_F = E[\int_{\mathbb{R}_+^2} \tau(x, y) F(dx \ dy)] \) is the average duration between price changes after a price increase, \( \tau_{\tilde{F}} = E[\int_{\mathbb{R}_+^2} \tau(x, y) \tilde{F}(dx \ dy)] \) is the average duration between price changes after a price decrease.
Diffusion limit of the price

**Theorem (R.C, & de Larrard, 2010)**

- **When** $\rho = 0$,

\[
\left( \frac{s(n \log n t)}{\sqrt{n}} \right)_{t \geq 0} \Rightarrow \sigma B
\]

where

\[
\sigma^2 = \frac{\pi \delta^2 v^2 \lambda}{D(F)} D(F) = \int_{\mathbb{R}^2_+} xy dF(x, y).
\]

- **When** $\rho < 0$,

\[
\left( \frac{s(n t)}{\sqrt{n}} \right)_{t \geq 0} \Rightarrow \sigma B
\]

where

\[
\sigma^2 = \frac{\delta^2}{m(f, \sigma_Q, \rho)}, \quad m(f, \sigma_Q, \rho) = \mathbb{E}[\tau_f]
\]

is the expected hitting time of the axes by $B_f$. 

**Rama Cont & Adrien de Larrard**

**Price Dynamics in Limit Order Markets**
The variance of price increments at time scale $\tau_2 \gg \tau_1$ is thus given by

$$\sigma^2 = \frac{p}{1 - p} \frac{\tau_2}{\tau_1} \frac{\pi \delta^2 \nu^2 \lambda}{D(f)}$$

$$D(f) = \int_{\mathbb{R}_+^2} xydF(x, y).$$

So: intraday volatility emerges as a tradeoff between

- average rate of fluctuation of the order book: $\lambda \nu^2$
- a measure of order book depth: (multiplicative) average of bid and ask queue size $D(f) = \int_{\mathbb{R}_+^2} xydF(x, y)$
- a measure of order book asymmetry: $p =$ probability of two consecutive price changes $\rightarrow$ mean reversion

Same expression as when orders are generated by Poisson processes!
Link between volatility and order flow: empirical test

Figure: Empirical std deviation of 10 min returns vs theoretical prediction of volatility based on diffusion limit of queueing model for SP500 stocks.
Flash Crash

When sell orders exceed buy orders by an order of magnitude, the price acquires a negative trend and drops linearly and this the deterministic trend of the price dominates price volatility. If

\[
\left( \mathbb{E}[V_{1}^{n,b}], n^{\beta} \mathbb{E}[V_{1}^{n,a}] \right) \xrightarrow{n \to \infty} (\Pi^{b}, V^{a}) \quad \text{with} \quad \Pi^{b} < 0 \quad \text{and} \quad V^{a} \geq 0,
\]

\[
\frac{T_{1}^{n,b} + \ldots + T_{n}^{n,b}}{n} \to \frac{1}{\lambda^{b}}, \quad \frac{T_{1}^{n,a} + \ldots + T_{n}^{n,a}}{n} \to \frac{1}{\lambda^{a}},
\]

\[
n^{2} \tilde{f}_{n}(n, n) \Rightarrow \tilde{F}.
\]

then

\[
\left( \frac{S_{[nt]}^{b}}{n}, t \geq 0 \right) \Rightarrow \left( \frac{\lambda^{b} \Pi^{b}}{\int_{\mathbb{R}^{2}} y \tilde{F}(dx, dy)} t, t \geq 0 \right).
\]
Conclusion

- Limit order book may be modeled as queueing systems
- Asymptotic methods (heavy traffic limit, Functional central limit theorems) give analytical insights into link between higher and lower frequency behavior, between order flow properties and price dynamics.
- General assumptions: finite second moment of order sizes, finite first moment of quote durations and weak dependence, allows for dependence in order arrival times and sizes
- Allows for dependent order durations, dependence between order size and durations, autocorrelation, ...
- Explicit expression of probability transitions of the price
- Distribution of the duration between consecutive price moves
- Different regimes for price behavior depending on the correlation between buy and sell order sizes
- Expression of the volatility of the price as a function of orders flow statistics
